Abstract
Background: Cell therapies explore unmet clinical needs of patients with chronic kidney disease with the potential to alter the pathway toward end-stage kidney disease. We describe the design and baseline patient characteristics of a phase II multicenter clinical trial utilizing the novel renal autologous cell therapy (REACT), by direct kidney parenchymal injection via the percutaneous approach in adults with type 2 diabetic kidney disease (T2DKD), to delay or potentially avoid renal replacement therapy. Design: The study conducted a prospective, multicenter, randomized control, open-label, phase II clinical trial between an active treatment group (ATG) receiving REACT from the beginning of the trial and a contemporaneous deferred treatment group (DTG) receiving standard of care for 12 months before crossing over to receive REACT. Objectives: The objective of this study was to establish the safety and efficacy of 2 REACT injections with computed tomography guidance, into the renal cortex of patients with T2DKD administered 6 months apart, and to compare the longitudinal change in renal function between the ATG and the DTG. Setting: This was a multicenter study conducted in major US hospitals. Patients: We enrolled eighty-three adult patients with T2DKD, who have estimated glomerular filtration rates (eGFRs) between 20 and 50 mL/min/1.73 m². Methods: All patients undergo an image-guided percutaneous kidney biopsy to obtain epithelial phenotype selective renal cells isolated from the kidney tissue that is then expanded ex vivo over 4–6 weeks, resulting in the REACT biologic product. Patients are randomized 1:1 into the ATG or the DTG. Primary efficacy endpoints for both study groups include eGFR measurements at baseline and at 3-month intervals, through 24 months after the last REACT injection. Safety analyses include biopsy-related complications, REACT injection, and cellular-related adverse events. The study utilizes Good Clinical and Manufacturing Practices and a Data and Safety Monitoring Board. The sample size confers a statistical power of 80% to detect an eGFR change in the ATG compared to the DTG at 24 months with an α = 0.05. Limitations: Blinding cannot occur due to the intent to treat procedure, biopsy in both groups, and open trial design. Conclusion: This multicenter phase II randomized clinical trial is designed to determine the efficacy and safety of REACT in improving or stabilizing renal function among patients with T2DKD stages 3a–4.
Introduction

Cell therapies attempt to address unserved clinical expectations and needs of patients and medical professionals for various chronic medical conditions, including chronic kidney disease (CKD) [1, 2]. CKD affects about 18% of the world population (850 million individuals), with up to 50% secondary to type 2 diabetes which encumbers large cost expenditures, given its risk for progression to end-stage kidney disease [3–5]. Current type 2 diabetic kidney disease (T2DKD) treatments such as renal angiotensin system inhibitors and SGLT2 inhibitors utilize small molecules to modulate biochemical mechanisms of action, albeit in a damaged structural environment [6–8]. In comparison, cell therapies have the potential to induce structural nephro-restoration to stabilize or improve renal function with infrequent dosing and few or no immunologic concerns [9–11].

Most cell-based therapies under investigation for CKD utilize intravascular-delivered mesenchymal cell lines with variable dosing, potency, stability, and end-organ effect. REACT endeavors to address these shortfalls by using a personalized treatment approach with autologous, homologous cells intended to restore nephron structure, improve kidney function, and decrease CKD-related morbidities. REACT consists of selective renal cells (SRCs) isolated and expanded using Good Manufacturing Process (GMP) from kidney biopsy tissue obtained from CKD patients.

Our preclinical experience with renal autologous cells demonstrated improved renal function and nephron repair, based on surrogate markers and histologic findings in diabetic models [12]. A first-in-human phase I trial in moderate to advanced T2DKD patients confirmed cell safety and stabilization of various renal function surrogate markers during laparoscopic-guided direct renal cortex REACT delivery [13]. We herein report the design of a novel phase II open-label cell therapy trial of REACT, whereby expanded autologous renal cells are percutaneously reinjected into patients with T2DKD stages 3a–4, in a specific locoregional site of the kidney identified with computed tomography (CT) imaging. Our clinical trial design is shown in Figure 1 and is registered at the following website: https://clinicaltrials.gov/ct2/show/NCT02836574.

Our clinical trial objectives are to establish the efficacy and safety of 2 image-guided percutaneous injections of REACT into the renal cortex of patients with T2DKD, administered 6 months apart, and to compare the change in renal function between an active treatment group (ATG) and a contemporaneous deferred treatment group (DTG).

Materials and Methods

Trial Design

This is a prospective, multicenter, randomized control, open-label, phase II clinical trial. Patients were randomized in a 1:1 ratio into 2 groups (ATG n = 42 or DTG n = 41) after manufacturing confirmed the adequacy/quality of the donor kidney biopsy material and the date of REACT injection. Randomization was performed with the Interactive Web Randomization System. Since this is an open-label study, the study participants, investigators, site staff, and sponsor are not blinded to the treatment assignment. Following a kidney biopsy, patient randomization takes place into the ATG or DTG cohorts. The ATG receives REACT treatment from the beginning of the trial, whereas the DTG will receive SOC for 12 months before crossing over to receive the REACT treatment.

Participants

We included 83 patients, ages 30–80 years, who have T2DKD and an established declining estimated glomerular filtration rate (eGFR) between 20 and 50 mL/min/1.73 m² (CKD stages 3a–4). Patients are from 17 institutions in the USA. To define the rate of CKD progression, baseline renal function was determined by 2 or more eGFR measurements, at least 3 months apart and 18 months pre-intervention. Patient demographics including clinical/laboratory characteristics and concomitant medications are shown in Table 1. The patient’s blood pressure must be <150/90 mm Hg on stable doses of antihypertensives (defined as dose adjustment to no less than one-half of the current dosage or to no more than 2 times the current dosage), 6 weeks prior to the REACT injection, but dose interruptions for up to 7 days due to medical necessity are allowed. If their antihypertensives included an angiotensin-converting enzyme inhibitor or an angiotensin receptor blocker, treatment must have been initiated at least 8 weeks prior to their renal biopsy. Participants refrain from consuming nonsteroidal anti-inflammatory drugs (including aspirin), fish oil, platelet inhibitors, and anticoagulants 7 days before and after the renal biopsy and REACT injections. Inclusion and exclusion criteria are described in Table 2.

Biopsy and REACT Injection Procedures

All patients underwent an outpatient percutaneous renal biopsy and then were randomized to either the ATG or the DTG of the trial. ATG patients receive a REACT dose as soon as REACT is manufactured and delivered to the research site, whereas the DTG patients received the intervention after 12 months of SOC treatment. Patients received 2 injections of REACT given 6 months apart. In addition, each patient’s rate of renal function change (based on the previous 18 months) serves as a comparator to establish the rate of DKD progression. Furthermore, the DTG patients serve only as contemporaneous comparators to the ATG patients for the 12 months during SOC treatment and against themselves once they cross over to receive REACT. The final statistical analysis will reflect the comparator time line and account for expected progression of CKD in the DTG.

A selective population of renal cells are obtained from the patient’s renal cortex via percutaneous kidney biopsy, using a standard-of-clinical-care image-guided method (ultrasound or CT). Two 16-gauge or 4 18-gauge core samples >1.5 cm in length are obtained and placed immediately in the transport medium and
Key entry criteria
- Type 2 diabetes mellitus (DKD)
- Male or female 30–80 years of age
- eGFR ≥ 20 and ≤ 50 mL/min/1.73 m²
- Not on renal dialysis, HbA1c <10%

Follow-up visits conducted at 3-month intervals after month 3 post 2nd REACT® injection until end of study (after 24 months)

Fig. 1. Trial design outline. R occurs after kidney biopsy into ATG or DTG. The deferred group receives REACT following 12 months of SOC. R, randomization; SOC, standard of care; REACT, Renal Autologous Cell Therapy; ATG, active treatment group; DTG, deferred treatment group; DKD, diabetes kidney disease.

### Table 2. REACT for type 2 diabetes mellitus chronic DKD: clinical trial inclusion and exclusion criteria

**Inclusion criteria**

- The participant is male or female, 30–80 years of age on the date of informed consent
- The participant has an established diagnosis of T2DM
- The participant has an established diagnosis of diabetic nephropathy as the underlying cause of renal disease
- The participant has an established diagnosis of CKD not requiring renal dialysis, defined as having an eGFR between 20 and 50 mL/min/1.73 m² inclusive at the screening visit and prior to REACT injection
- The participant has blood pressure less than 150/90 at the screening visit, prior to renal biopsy, and prior to REACT injection(s). At the time of the biopsy and injections, the subject’s BP should not be significantly below the previously recorded stable pressure
- The participant has stable blood pressure and is maintained on a stable anti-hypertensive medication regimen if treatment for hypertension is necessary. If treatment includes an ACEi or an angiotensin receptor blocker, that treatment must have been initiated at least 8 weeks prior to renal biopsy. Treatment must be stable during the 6-week period immediately prior to REACT injection. Stable treatment is defined as dose adjustment to no less than one half of the current dosage or to no more than 2 times the current dosage. Dose interruptions up to 7 days due to medical necessity are allowed
- A minimum of 2 measurements of eGFR or serum creatinine should be obtained at least 3 months apart prior to the screening visit or within the previous 18 months to define the rate of progression of CKD. The subject should have adequate historical clinical data to provide a reasonable estimate of the rate of progression of CKD. The medical monitor may be consulted to ensure that there are sufficient data
- The participant is willing and able to refrain from NSAID consumption (including aspirin) as well as clopidogrel, prasugrel, or other platelet inhibitors during the period beginning 7 days before through 7 days after both the renal biopsy and REACT injection(s)
- The participant is willing and able to refrain from consumption of fish oil and platelet aggregation inhibitors, such as dipyridamole (i.e., Persantine®), during the period beginning 7 days before through 7 days after both the renal biopsy and REACT injection(s)
- The participant is willing and able to cooperate with all aspects of the protocol
- The participant is willing and able to provide signed informed consent

**Exclusion criteria**

- The participant has a history of type 1 diabetes mellitus
- The participant has a history of renal transplantation
- The participant has a serum HbA1c level greater than 10% at the screening visit
- The participant has uncontrolled diabetes (defined as metabolically unstable by the investigator)
- The participant has abnormal coagulation status as measured by APTT, PT-INR, and/or platelet count at the screening visit
- The participant has a bleeding disorder(s) or is taking anticoagulants, such as warfarin or direct thrombin inhibitors that, in the judgment of the investigator, would interfere with the performance of study procedures
- The participant has small kidneys (average size less than 9 cm) or has only one kidney, as assessed by ultrasound and/or MRI prior to renal biopsy, unless earlier radiology reports (generated within 1 year of the screening visit) are made available to confirm kidney size and number
- The participant has known allergy(ies) or contraindication(s) or has experienced severe systemic reaction(s) to kanamycin or structurally similar aminoglycoside antibiotic(s)
- The participant has a history of anaphylactic or severe systemic reaction(s) or contraindication(s) to human blood products or materials of animal origin (e.g., bovine and porcine)
- The participant is not a good candidate to undergo percutaneous REACT injection, in the judgment of the surgeon or physician who will perform the procedure. This includes individuals who are morbidly obese (defined as BMI greater than 45 kg/m²), have excessive fat surrounding the kidney, or who are otherwise at excessive risk for serious complications
- The participant has a history of severe systemic reaction(s) or any contraindication to local anesthetics or sedatives
- The participant has a clinically significant infection requiring parenteral antibiotics within 6 weeks of REACT injection
sent to the GMP facility for processing. An additional biopsy for local site histopathologic evaluation is allowed at the discretion of the investigator after obtaining the required cores for REACT manufacturing, depending on benefit versus risk of bleeding complications.

Selective Epithelial Renal Cell Isolation and Expansion: The cells are isolated by enzymatic digestion and expanded ex vivo, using standard cell culture techniques over approximately 4 weeks. SRCs are selected by density gradient centrifugation and formulated to produce REACT. REACT is shipped overnight as a thermostabile gelatin-based hydrogel fresh product to the clinical site, to be administered within 72 h from manufacturing release. REACT is warmed to room temperature for 30 min before the image-guided percutaneous injection into the patients’ renal cortex of the same donor kidney, typically targeting a lower pole region. A 20-gauge outer guide needle (COOK Inc, Bloomington, IN, USA) is inserted into the subcapsular kidney, followed by co-axial insertion of an inner noncutting pencil tip 25-gauge needle (IMD, Huntsville, UT, USA) into the renal cortex within 5 mm of the renal capsule as shown in Figure 2. The injection target is a few millimeters deep to the subcapsular region to maximize cell deposition within the cortex microenvironment of the REACT source. The procedure is performed in an outpatient setting and with moderate sedation. Proceduralists undergo training, certification, and onsite proctoring.

The dose of REACT is $3 \times 10^6$ cells/g estimated kidney weight by volumetric imaging analysis from a noncontrast MRI scan of the kidneys, obtained during patient screening. An individualized dose volume is predetermined and divided into multiple REACT deposits into the kidney. We conduct real-time assessment of nee-

REACT, Renal Autologous Cell Therapy; ACEi, angiotensin-converting-enzyme inhibitor; ARB, angiotensin receptor blocker; PT-INR, prothrombin time-international normalized ratio; DKD, diabetic kidney disease; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; APTT, activated partial thromboplastin time; HIV, human immunodeficiency virus; HBV, hepatitis B virus; HCV, hepatitis C virus; TB, tuberculosis; IUDs, intrauterine devices.
was calculated based upon the phase I trial using an 80% power. Eighty-three patients who satisfied all the inclusion criteria were randomized 1:1 into either treatment group. The sample size was calculated based upon the phase I trial using an 80% power with an α = 0.05, assuming a 33% dropout rate to detect a difference of 50% in the eGFR between groups, as the primary efficacy endpoint. The trial size also allows sufficient safety information from the procedures and REACT product to be collected.

Statistical Analysis
Utilizing eGFR slope, standard error, and sample size for each study arm, a two-sample Walsh t test will compare renal function and disease progression by CKD-EPI eGFR (2009), serum Cr, cystatin C, BUN, and urinary albumin at prerandomization, and through 24 months post-REACT injection. Patients will serve as their own control. The significance level of α = 0.05 will be set. We will evaluate the mean and standard deviation of the eGFR slope over time and at each endpoint, using a t test to determine the difference between the ATG and the DTG. Values for missing data will not be imputed. χ² analysis will compare the number of patients who experience AEs in both study groups.

The complete analysis set will include all patients enrolled in the study. The injection analysis set will include all patients who receive at least 1 REACT injection. Subgroup analyses will be performed to compare the safety and efficacy data from patients who received only a single REACT injection (e.g., due to exclusion criteria occurrences, dropout, death, or other reasons) versus patients who receive 2 REACT injections. Patient disposition (including screen failure, enrolled, successful biopsy, group assignment, number of REACT injections, withdrawn pre-injection or post-injection reasons, lost to follow-up, or completed study) will be summarized for the full analysis set by frequency and the proportion of patients.

Clinical and laboratory AEs will be coded using the Medical Dictionary for Regulatory Activities System Organ Class and Preferred Term, and we will present this information summarized. Treatment-emergent AEs by seriousness, intensity, the site investigator’s assessment of relationship to the kidney biopsy, REACT injection procedure or REACT product, patient discontinuation due to AEs, or deaths will be included. The number of events (occurrence) and the number of participants (incidence) who experienced AEs will be reported. The number and percent of patients who develop clinically significant laboratory abnormalities longitudinally or exhibit changes on their physical examinations will be summarized.

Clinical Outcomes
The primary objective is to assess the safety and efficacy of up to 2 percutaneous REACT injections delivered 6 months (+4 weeks) apart, into the donor kidney. The primary safety endpoint is to assess procedure- and REACT product-related adverse events through 24 months after the last REACT injection, and the primary efficacy endpoint is the measurement of eGFRs from prerandomization through 24 months after the last REACT dose. Renal-specific AEs will be monitored. Other laboratory parameters, including urinary albumin, serum BUN, and urine microalbumin/creatinine and protein/creatinine ratios, were obtained prerandomization and through 24 months after the last REACT injection. Noncontrast MRI and renal scintigraphy imaging are performed during the trial to assess morphologic change and analysis of split renal function between treated and nontreated kidneys.

Patient-Reported Outcomes
Quality of life and patient satisfaction surveys are used as subjective patient assessments. Patient-reported outcomes from the kidney disease quality of life (KDQOL) and EQ-5D-5L surveys...
were obtained at baseline (defined as after randomization and before REACT injection) and through 24 months after the last REACT injection. A two-sample t test will compare mean KDQOL and EQ-5D-5L scores between groups using a significance level of $\alpha = 0.05$. Each patient’s baseline KDQOL and EQ-5D-5L scores will be compared against the individual patient’s scores obtained through 24 months after the last REACT injection.

**Data Safety and Monitoring**

An independent Data and Safety Monitoring Board (DSMB) has been chartered to oversee patient safety, especially related to unexpected investigational product-related events. The DSMB consists of 3 members with expertise directly related to protocol-specified activities. It functions independently, and its members have no other engagement with the study sponsor. The DSMB meets at regular intervals depending on the rate of patient enrollment and new data generated, and advises the sponsor on aspects concerning the safety of patients participating in the clinical trial, specifically before the patients in the DTG receive their initial REACT injection. The DSMB reviews all safety and efficacy data obtained from interim analysis and may advise on dosing plans, protocol-specified evaluations, and follow-up procedures. The DSMB shares its recommendations with the study centers, institutional review boards/ethics committees, and regulatory authorities, as appropriate. Details of specific activities and responsibilities of the DSMB are in the DSMB charter.

**Discussion**

T2DKD imparts a large global burden on healthcare systems and economic costs to society. Diabetes may affect 25–28% of the US population by 2050, with >40% developing CKD, resulting in high-cost comorbidities including end-stage kidney disease and renal replacement therapy [5, 14, 15]. Since the advent of renin-angiotensin system inhibitors, multiple classes of small molecule drugs have entered the clinical development pipeline to reduce DKD comorbidities, while targeting biochemical pathways that modulate metabolic, anti-inflammatory, or hemodynamic responses [6, 16, 17]. Nephroprotective effects of recent DKD therapies have demonstrated modest early reductions in declining eGFRs, although none impart improvement in the structural repair of the nephron. In addition, small molecule drugs are usually ineffective in advanced stages of DKD. Our phase II multicenter clinical trial of the novel intervention REACT will assess the safety and efficacy of autologous, homologous cell therapy in T2DKD and attempt to demonstrate nephrorestorative improvement in renal function.

Our preclinical studies with experimental models of CKD including DKD-induced and nephrectomy CKD models, showed increased survival, augmented renal function, and improved comorbidities after the cortex in-
24 months, respectively, whereas cystatin C eGFR was lower at 12 and 24 months than screening levels.

Nine serious postprocedure adverse events were determined to be related to the surgical procedures with general anesthesia in the Phase I study. No conclusive adverse events were associated with the cell-based product [13].

In the present phase II clinical trial, we converted the laparoscopic injection to a CT-guided percutaneous approach, given the advances in minimally invasive procedures with smaller-platform medical devices, imaging methods, and conscious sedation in an outpatient setting. These changes will mitigate adverse procedural events, and image guidance will ensure REACT enters the renal cortex. This approach currently is also used in a phase I open label trial of CKD due to congenital anomalies of the urinary tract [24].

Conclusions

REACT holds the promise to achieve improved renal function by nephron-repair and restoration of the diseased kidney with its unique cell composition and delivery method. The anti-fibrotic, anti-inflammatory, and non-immunologic features of REACT may ameliorate the progression of DKD and reduce the need for renal replacement therapy. An improved structural function could complement and enrich the bioactivity of other small molecules affecting T2DKD renal function and comorbidities.

Acknowledgements

We wish to thank our REACT trial participants for their generous support of CKD research. We also would like to thank Ms. Brenda McGrath for statistical management and analysis, Ms. Chelsey Hehl for data administration assistance, and Ms. Beth Hilburger for manuscript preparation, all from ProKidney.
